## Keywords

Initial and key demographic and gear selectivity parameters; review, sampling and estimation; population dynamics; stock assessment; biological and ecosystem modelling; mesopelagic species; Pearlside (Maurolicus muelleri); Glacier Lantern Fish (Benthosema glaciale);

## Executive Summary

The Deliverable D5.2 Report on Initial Demographic Parameters compiles information and data on key demographic parameters and gear selectivity parameters to be used to parameterize the stock assessment and biological community and ecosystem-based models and methods applied under MEESO WP5. This covers input to parameterization of i) the population dynamic and length based single stock assessment methods in the form of the TrophFishR and S6 models, ii) the StrathSPACE spatially explicit single-species models for target mesopelagic fish species, iii) the NORWECOM.E2E model for the food-web and vertical carbon flux, and iv) the SEAPODYM model for biomass and dynamics of mesopelagic functional groups.

The report presents a review of existing information on key demographic parameters from published literature as well as current outputs so far collated from MEESO. This includes outputs from the work packages (WPs) on fishing technology development with respect to e.g. gear selectivity parameters influencing length (and age) frequency sampling (MEESO WP3), and the field campaign data sampling with provision and estimation of initial biological parameters (MEESO WP4). The field campaign data also includes other research survey sampling (MEESO WP2), and sampling from commercial fishery (MEESO WP3 in cooperation with MEESO WP5). This is done in order to provide initial parameters and fitting data for the WP5 modelling tasks for the main species and stocks focused upon in the project, i.e. especially Benthosema glaciale and Maurolicus muelleri. These initial parameters will be updated later during the continued course of the field campaign and field data analyses. It should be emphasized that these parameters are initial and only very preliminary and that analyses are still ongoing on the input data from the MEESO research survey and different periods of commercial fishery sampling. Because the stock identities and delineations, as well as the migration patterns of the two species, are not fully known from the incomplete coverage of the sampling in the various existing studies, it is not known to which extent all stocks and stock
components (life stages) are covered according to the presented parameters in this report. Accordingly, the parameters should overall be used with great caution.

For example, the key requirements for the assessment models (MEESO Task 5.2, T5.2) are population length distributions obtained from surveys, technologicall or commercial trial fishery haul catches, and from acoustic survey data; estimates of the maturity ogive (proportion mature at size); weight-length relationship; and size selectivity of fishing gear. Life-history parameters (allometric exponent, energy allocation to activity and reproduction, recruitment efficiency) also required for T5.2 (and T5.3 below). The latter can also be obtained from the literature on related taxa and established life-history scaling rules. Using age-given-length data from surveys or commercial trial fisheries, natural mortality rates will be obtained from vertical lifetable analysis in order to provide estimates independent of those of the purely sizebased methods in T5.2. The spatial and ecosystem models in T5.3 will explore climate change scenarios which require the additional quantification of growth and/or mortality rates as functions of temperature and/or food availability. For the latter stomach content data, survey estimates of prey availability, and existing digestion rate models will be used to provide the best available estimates of feeding rate parameters of key taxa as a function of the prey field and temperature.

### 1.0 Literature Review on Key Demographic Parameters for Pearlside (Maurolicus muelleri)

### 1.1 Introduction

The silvery lightfish or pearlside Maurolicus muelleri is a small planktivorous mesopelagic fish inhabiting global oceanic waters, and largely concentrated in the temperate waters of the Atlantic and Pacific Ocean (FishBase, 2020). The lightfish is a short-lived species with a lifespan of about 3 years and maximum length of 7 cm (Gjösæter, 1981). Maturity is reached after one year of juvenile life and fecundity is high (Salvanes and Sockley, 1996). Maurolicus muelleri feeds on copepods and euphausiids, and is itself predated on mainly by blue whiting and saithe (Gjösæter, 1981). Feeding and predatory avoidance strategies in lightfish involve diel vertical migration. The species makes use of light intensity to regulate their vertical distribution in the water column, residing closer to the surface at night and deeper in the water column during daylight (Staby et al., 2011). Its depth ranges from 50 to 400 meters, and is dependent on the ontogenetic phase of the individuals and on the time of day (Dalpadado and Gjösaeter, 1987; Staby et al., 2013). Together with the northern lanternfish Benthosema glaciale, the species is the most abundant mesopelagic fish in Norwegian and North Atlantic waters (Rasmussen and Giske, 1994). Following the abundances and the distribution profiles, the two fish species represent suitable and appealing targets for mesopelagic fishery activities. Due to the high body content of valuable omega-3 polyunsaturated fatty acids, the species is mainly targeted for industrial purposes involving processing the harvested resources for fish meal, oil production and nutraceuticals (Prellezo, 2019).

### 1.2 Review Results and Overview

Table 1.1. Parameters of life-history traits and biology of pearlside Maurolicus muelleri at different locations in different periods from the published literature. The outcome of the literature review shows that research has been mainly focused on North-East Atlantic waters. Additional available information on taxonomically-close species Maurolicus stehmanni are added for comparison.

Sobradillo et al., $2019 \rightarrow$ A vertical distribution profile is available. No length-frequency distribution graph displayed.

Kristoffensen, $2007 \rightarrow$ Temperature was recorded at sampling depth but not shown in a table. Temperature was about 1 degree lower in the open waters compared to the fjords environment.

Kristoffensen and Salvanes, $1998 \rightarrow$ Temperature was recorded at sampling depth but not shown in a table. The temperature regime experienced by the fish is different in the open sea than in the fjords. In the fjords, the temperature at different water layers is stable and similar in values from one fjord to another. The open waters have a warmer upper layer and a colder deeper layer. Mean instantaneous mortality rate ( $Z$ ) was estimated from the slope of the catch curve over age classes (4-5 classes used). Assumptions include: constant rate of mortality, no recruitment variation and no gear selection. Abundances of fish were found to decline with latitude. There are three location-specific length distribution graphs available.

Salvanes and Sockley, $1996 \rightarrow$ Maurolicus muelleri is described as a rapidly maturating species which lives a short life of up to about 3 years. The Age-1+ group locates in the upper part of the SSL while age-2+ locates in the lower part of the layer. There is a length-frequency distribution graph available for each of the four areas.

Goodson et al., $1995 \rightarrow$ There are length-frequency distributions graphically available in the paper, distinguished for January, March, May and June. The graphs show the gradual overlapping of year-classes in the water column distribution (neatly separated upper and lower layers), with juvenile age-0 merging the adult population in the SSL when approaching summer. Growth rate was higher in January than in June, thus the size differences between juvenile and adults decreased towards summer. The vertical distribution is characterized by ascent at dusk and descent at dawn. Seasonality (strong at such high latitude) strongly influences the species' behaviour. The pattern of vertical migration also shifts seasonally, depending on whether survivorship, in winter, or reproduction, in summer, is the predominant motivation.

Rasmussen and Giske, $1994 \rightarrow$ The annual mortality rate between age-1 and age-2+ was calculated from the length-frequency distribution assuming equal year-class strength. It should therefore be considered with caution. The age classes identified go from 0 to $3+$, and with some individuals potentially of age-4. A plot of length-frequency distribution is available in the paper. In May, the vertical distribution profile consists of: max depth of SSL between 11:00 and 15:00 in the afternoon (lowest depth at 14:15 pm); min depth of SSL between 23:30 and 3:30 at night. Stomach content analysis available. During the summer, the fish locate between 120 and 170 metres during the day, while between 0 and 30 metres at night. In winter, juvenile stays between 70 and 100 metres during the day but the adults locate 50 metres deeper in the lower layer.

Gjösæter, $1981 \rightarrow$ The mortality is calculated from length-distribution over age classes (I-IV) through geometric mean regression, but they underline a gear selection bias. High mortality between 2-3 years old individuals is highlighted in the summer. Growth was found higher in the fjords compared to the open ocean, and the Linf value seemed lower in the fjords. Production per year is estimated to be $0.23 \mathrm{~g} /$ fish. The method used assumes that the mortality is constant. In reality, the natural mortality seems to be low during the first part of life when production is high, and higher during older ages, when growth, and therefore production, is very slow. These effects will tend to make $\mathrm{P}=0.23 \mathrm{~g}$ an underestimate. Further stomach analyses are available in the paper. The maximum sustainable yield was calculated to occur at a fishing mortality of between 5 and 6 , with an age of 0.6 years at first capture. Age at recruitment is considered to be 0.25 and max age is 3.5 years.

Giske and Aksnes, $1992 \rightarrow$ This paper is not included in the table above but contains information on feeding rate, growth rate, and parameters, but not in terms that correspond to those of the table.

Young et al., $1987 \rightarrow$ The temperature profile at 200 m is available in graphic form. Two tables with sex-grouped frequencies for each SL class are available in the paper. The sex ratio was consistent among size classes with females always outnumbering males. The spawning season is prolonged from August to October. Different eggs development coexisted in time underlying a batch spawning behavior.

Dalpadado and Gjøsaeter, $1987 \rightarrow$ This paper includes scarce information on the zooplankton community and diet. The fish locate between 350 and 450 during the day but some schools of Maurolicus were observed between 50 and 200 during the day. A table with sex-grouped frequencies for each SL class is available in the paper.

Clarke, $1982 \rightarrow$ A graphical representation of the size-classes harvested along the depth profile is available. Length-frequencies (not good for extraction but only for visualization) among the sampling months is available.

Prosch, $1991 \rightarrow$ Spawning in the Benguela area peaks in spring/early summer. Yearly temperature profile at 40 metres available, with further references in the text to other studies which determine hatching temperatures and spawning preferences.

Melo and Armstrong, $1991 \rightarrow$ This paper is not included in the above table, but it contains some information about fecundity of Maurolicus muelleri in the Benguela ecosystem in 1989. Fecundity was calculated over standard length and resulted in the equation $y=3.52 x+41.14$. Mean relative fecundity was found to be 203 eggs/g (ovary-free fish) or $182 \mathrm{eggs} / \mathrm{g}$ (whole fish).

Almeida and Rossi-Wongtschowski, $2007 \rightarrow$ A table of size-classes frequency distribution is available. No significant sex ratio different from 1:1 was found overall. Description of the use of $L 50 / L_{\text {inf }}$ ratio information and its approximation to $L_{\min }(o b s$. at maturity $) / L_{\max }($ observed $)$.

Staby et al., $2013 \rightarrow$ Three SSLs are identifiable by the echogram. SSL1 is situated at 50-60 metres and is composed of post-larvae, SSL2 is situated at 66-80 metres and is composed of juveniles, and SSL3 is at 110-165 metres and composed of adults. SSL1 and SSL2 displayed ascent towards the surface, reaching it at sunset, and descent towards their usual depth, reaching it before sunrise. The SSL3 layer mainly remained at constant depth. The mortality over feeding rate ratio is smaller for post-larvae than for juveniles and adults. This is because at higher light intensity the larvae feed at higher rate, and consequently grow at higher rates, and experience a smaller mortality rate for their reduced dimensions (less susceptible to visual predation). Instead in deeper layers and larger individuals still have a high feeding rate but also the predation rate by visualization increases.

Staby et al., $2011 \rightarrow$ Length-frequency distributions are available in the paper, separated by day and night, for SSL and for two years. Temperature and salinity profiles are also available. Catches in kg are available for each trawl sample. The observed vertical distributions consisted of 3 layers in 2007: two at 50-75m and one at 115-175m during daytime. In 2008 the layers were 3 neatly separated in $70-90 \mathrm{~m}, 110-125 \mathrm{~m}$ and 155-215 m. Above 200 m the catches were dominated in biomass by Maurolicus. Monthly-based 24h-echograms are available.

### 2.0 Literature Review on Key Demographic Parameters for Glacier Lantern Fish (Benthosema glaciale)

### 2.1 Introduction

The glacier lantern fish or Benthosema glaciale is a small planktivorous, non-migratory mesopelagic fish inhabiting Atlantic oceanic waters, mainly concentrating in the northern Atlantic Ocean (FishBase, 2020). The species has a wide temperature tolerance and is mainly present in waters with temperatures between $4-16^{\circ} \mathrm{C}$. The geographical distribution limits in the southern Atlantic and in the Eastern Mediterranean correspond closely to the $15^{\circ} \mathrm{C}$ isotherm of average annual temperature at 200 m (Gjösæter, 1973; Schroeder, 1963). The glacier lantern fish is a short-living species with a maximum life span of about 8 years (Muus \& Nielsen 1999), a small body size with a maximum length of 10.3 cm (Hulley, 1990), a high growth rate and a small size at maturation (García-Seoane et al., 2014). During the winter season however, growth in body length slows or nearly ceases (Kawaguchi \& Mauchline, 1982). Maturation is reached at the age of 2 or occasionally 3 years (Gjøsæter, 1981).

Benthosema glaciale feeds mainly on Copepods (Kawaguchi \& Mauchline, 1982). Distinct vertical migrations occur with high abundances at lower depths (150-530 m) during the day and closer to the surface during the night ( $45-90 \mathrm{~m}$ ) to feed on zooplankton (Halliday, 1970). The glacier lantern fish is mainly predated on by gadoid fish, such as saithe and blue whiting (Dypvik \& Kaartvedt, 2012). The diel vertical migration is a trade-off between feeding opportunities and predation risk, with light being the trigger mechanism (Dypvik \& Kaartvedt, 2012; Pearre, 2003). Together with the northern pearlside Maurolicus muelleri, the species is the most abundant mesopelagic fish in Norwegian and North Atlantic waters and together they are therefore the most attractive targets for mesopelagic fishery activities (Rasmussen \& Giske, 1994).

### 2.2 Review Results and Overview

Table 2.1. Parameters of life-history traits and biology of glacier lantern fish or Benthosema glaciale at different locations in different periods from the published literature. The outcome of the literature review shows that research has been mainly focused on North-East Atlantic and North-West Atlantic waters.

### 3.0 Key Demographic (Biological) Parameters for Pearlside (Maurolicus muelleri) and Glacier Lantern Fish (Benthosema glaciale) Collated and Estimated from MEESO Survey Sampling (Work Packages 4 \& 2 \& 5)

### 3.1 Introduction

This section contains the initial parameters obtained so far from outputs on the field campaign data sampling with provision and estimation of initial biological parameters under the survey sampling associated to the MEESO project (MEESO WP4 \& WP2 \& WP5). It should be emphasized that these parameters are initial and only very preliminary, and that analyses are still ongoing on the input data from the MEESO research survey sampling. Accordingly, the parameters should be used with great caution.

## 3．2 Initial Results and Overview from Research Survey Sampling

Table 3．1．Parameters of life－history traits and biology of pearlside（Maurolicus muelleri）and glacier lantern fish（Benthosema glaciale）obtained at different locations and in different periods from the MEESO research survey sampling．

# 3.3 Additional Relevant Information Available on Key Demographic Parameters for Pearlside (Maurolicus muelleri) from Survey Sampling 

## Biology and key demographic parameters of Maurolicus muelleri in the Bay of Biscay. Preliminary results.

By Paula Alvarez, Dorleta Garcia and Guillermo Boyra.

#### Abstract

Based on the catches of $M$. muelleri made with a pelagic trawl net during the surveys JUVENA (in September 2019/2020), MEGS (in April 2019) and BIOMAN (in May 2020) in the Bay of Biscay, we studied the most relevant biological parameters to assess the feasibility of developing an ecologically sustainable mesopelagic fish fishery. The study presents preliminary data on length distribution, the age, growth, maturity ogive, spawning season, and sex ratio for this species. The results revealed that in spring, the adult spawners (age 1 and 2) are the dominant ones, while in September, they are the juveniles (age 0) born in spring. No fish older than 2 years were found in this area. Growth in weight with length, described by the power equation, varied annually ( $\beta=3.01$ and $\beta=3.13$ for 2019 and 2020, respectively) but no statistically differences were found between sexes. Using standard lengths, $50 \%$ of fish were mature at 34.1 mm (both sexes combined) and the sex ratio, male to female, was 0.44:0.56. The proportion of females increased with length, and a $1: 1$ sex ratio was predicted at a standard length of 41.5 mm . Most of ripe female fish were found April and May and a few in September. The spawning season occurs, at least, between March and July with a likely peak in May. Batch fecundity ranged from 114 to 919 oocytes/females, and it increased with the weight and the length of females. These results can be considered a significant advance in the knowledge of the biology of $M$. muelleri in this area, despite the fact that some variables, such as age assignation, require more in-depth analysis.

### 4.0 Key Demographic (Biological) Parameters for Pearlside (Maurolicus muelleri) Estimated from Survey Data in TropFishR (MEESO Work Package 5)

### 4.1 Introduction

This section covers key demographic parameters for Pearlside (Maurolicus muelleri) estimated from survey data in TropFishR (MEESO Work Package 5). The table below presents the results from highly preliminary initial runs with the TropFishR package (Mildenberger et al. 2017). ELEFAN+ bootstrapping methods were applied to subsets of length frequency data from Maurolicus muelleri, from different regions and years. Growth parameters from the Von Bertalanffy equation, and their confidence intervals, were estimated, and for selected subsets also natural Mortality M and selectivity parameter L 50 . The results in the table below are presented with the main purpose of model calibration and parameter setting, and hence should be treated with extreme caution.

### 4.2 Initial Results and Overview from TrophFishR Analyses

### 6.0 Key Demographic (Biological) Parameters for Pearlside (Maurolicus muelleri) Collated and Estimated from Commercial Fishery Sampling (MEESO Work Package 3 \& 5)

### 6.1 Introduction

Initial parameters obtained so far from outputs on the field campaign data sampling with provision and estimation of initial biological parameters from the commercial fishery sampling associated to the MEESO project (MEESO WP3 \& WP5). It should be emphasized that these parameters are initial and only very preliminary and that analyses are still ongoing on the input data from the commercial fishery sampling associated to MEESO. Accordingly, the parameters should be used with great caution.

### 6.2 Initial Results and Overview from Commercial Fishery Sampling

Table 6.1. Commercial Fishery-available parameters of life-history traits and biology of pearlside (Maurolicus muelleri) at different locations in different periods from sampling of commercial fishery.

### 7.0 Initial Commercial Fishing Gear Selectivity Parameters for Pearlside (Maurolicus muelleri) and Glacier Lantern Fish (Benthosema glaciale) as Estimated from the Fishing Technology Development Work Package 3

### 7.1 Introduction

This section provides the initial parameters obtained as outputs so far from the MEESO WP3 on fishing technology development for commercial trawl fishing gears with respect to, e.g., gear selectivity parameters.

### 7.2 Results and Overview of Initial Gear Selectivity Parameters from MEESO WP3

The size selectivity of Pearlsides (Maurolicus muelleri) and Glacier Lantern Fish (Benthosema glaciale) of three commercial mesopelagic trawl designs used in WP3 (with and without smallmesh liners) was assessed as a function of mesh size (MS), tapering angle ( $\alpha$ ) and mesh opening angle (OA) following five key steps:

In step 1 we used samples of pearlsides collected in July 2019 on board the pelagic trawler "Birkeland" off the western coast of Norway ( $60^{\circ} 51^{\prime} \mathrm{N} 03^{\circ} 41^{\prime} \mathrm{E}$ ) using a Egersund 1200 m trawl. The samples of glacier lantern fish were collected in 2019, off the coast northern Norway ( $69^{\circ} 32^{\prime} \mathrm{N}$ and $18^{\circ} 02^{\prime} \mathrm{E}$ ), on board the research vessel "Johan Ruud" using a standard Campelen sampling bottom trawl. All the samples were selected to cover wide span of length sizes.

In step 2, we conducted fall-through experiments (Herrmann et al 2012; Herrmann et al 2021) to test which length sizes of fish can geometrically pass through the mesh templates of different MS and OA. A total of 311 pearlsides and 71 glacier lanternfish were length measured to the nearest mm and presented head first and optimally oriented to 54 different mesh templates. Optimal orientation implies that each fish is positioned in such a way that maximizes its chance to pass through each mesh template (Fig. 3). The mesh templates perforated in 5 mm thick nylon plate (Figure 3) included six different mesh sizes: $6 \mathrm{~mm}, 12 \mathrm{~mm}$, $16 \mathrm{~mm}, 20 \mathrm{~mm}, 24 \mathrm{~mm}$ and 30 mm . Some of these mesh sizes corresponded to the mesh sizes of the small-meshed liners used in the trawls. For each mesh size we had nine different
opening angles: $10^{\circ}, 20^{\circ}, 30^{\circ}, 40^{\circ}, 50^{\circ}, 60^{\circ}, 70^{\circ}, 80^{\circ}$ and $90^{\circ}$. The only force acting on the fish was gravity. Whether or not each fish passed through each mesh template was recorded as either a "yes" if it passed through the mesh template, or "no" if it did not (Fig 1).

Fig. 1: Fall-through experiment with optimally oriented pearlside.

In step 3, for each mesh template and length class ( 1 mm length class), the number of successful and unsuccessful passes were counted. The data were then treated as coveredcodend data (Wileman et al. 1996), where each fish that passed through the mesh template was considered to end up in the cover, while the others were treated as retained in the codend. The following logit size selection model was then fitted to each fall-through dataset to obtain a size selectivity curve for each mesh template:

$$
\begin{equation*}
r(L, l 50, S R)=\frac{e^{\frac{\ln (9)}{S R} \times(l-l 50)}}{1+e^{\frac{\ln (9)}{S R} \times(l-l 50)}} \tag{1}
\end{equation*}
$$

The I in (1) represents fish total length, 150 the length at which fish has $50 \%$ probability of being retained in the codend, $S R$ the selection range, which is equivalent to $I 75-125$. The estimated $I 50$ and $S R$ values, their covariance matrix, together with the corresponding $M S$ and $O A$ value for each mesh template were then used to establish the following predictive size selection model:

$$
\begin{aligned}
l 50 & =\alpha_{1} \times M S \times O A+\alpha_{2} \times M S \times O A^{2}+\alpha_{3} \times M S \times O A^{3}+\alpha_{4} \times M S \times O A^{4} \\
S R & =\beta_{1} \times M S \times O A+\beta_{2} \times M S \times O A^{2}+\beta_{3} \times M S \times O A^{3}+\beta_{4} \times M S \times O A^{4}
\end{aligned}
$$

(2)

The $\alpha_{1} \ldots \alpha_{4}$ and $B_{1} \ldots b_{4}$ in (2) are the model parameters that need to be estimated. All simpler sub-models obtained by leaving out one or more terms at a time from the (2) were also considered for predicting 150 and SR following the procedure described in Brčić et al. (2018) and Herrmann et al. (2021). From the total of 256 models for each species, the model with the lowest AICc value (AICc being the AIC (Akaike 1974) with a correction for finite sample size) was chosen as the best model.

In step 4, the best model for each species was applied to predict 150 and $S R$ values for each mesh template used in the fall-through experiment. To check for the model self-consistency, the model predictions were plotted together with their respective $95 \%$ confidence intervals against the $I 50$ and $S R$ values estimated by fitting a logit size selection model (1) to each fallthrough dataset. In case if predictions represent the trends in the fall-through data well, they were summarized in an isoline graph (lines with equal 150 values) called the design guides. The design guides depict how 150 values vary with the change in MS and OA (Brčić et al. 2018; Herrmann et al. 2021). While performing the fall-through experiments, we assumed that fish are optimally oriented when contacting the mesh. However, during the fishing, meshes are never perpendicular to the natural swimming path of the fish and fish often meet the meshes at suboptimal angle of attack (Fig 4). Fish that are good swimmers and are not exhausted from swimming in front of the trawl prior to entering it, are able to actively change their position to obtain optimal orientation and maximize their escapement probability. Knowing that pearlside and glacier lantern fish grow up to 8 cm and 10 cm , respectively, we assumed they encounter trawl meshes at suboptimal angle of attack (equal to, or close to the tapering angle of the section of the trawl where they encounter the meshes), and do not have enough strength to overcome a strong water flow inside the gear to actively change their position to obtain an optimal orientation and maximize escapement. As angle of attack/ tapering angle is decreasing towards the codend, the projection of the mesh is becoming narrower (Krag et al., 2014; Cuende et al., 2020) and fish are not able to fully utilize the mesh (Fig 2).

Fig 2. Illustration showing available mesh area as fish meets the mesh at optimal ( $90^{\circ}$, green) and suboptimal (blue) attack angle.

In step 5, we explored the effect of different angles of attack/tapering angles on the size selection of pearl side and glacier lantern fish in trawls. For each mesh size and opening angle considered, we calculated projected mesh size ( $m s$ ) and projected mesh opening angle (oa) for different angles of attack/tapering angles (Fig 4) using formulas (3) - (8). Angles considered ranged from $5^{\circ}$ to $90^{\circ}$, in steps of $5^{\circ}$.

$$
\begin{gather*}
\frac{M W}{2}=\frac{M S}{2} \times \cos \frac{o A}{2} \\
\frac{M L}{2}=\frac{M S}{2} \times \sin \frac{o A}{2} \\
\frac{m l}{2}=\frac{M W}{2} \times \sin T A \\
\frac{m W}{2}=\frac{M W}{2} \\
o a=\tan ^{-1} \frac{\frac{M W}{2}}{\frac{m l}{2}} \\
m s=\frac{2 \times \frac{M W}{2} \times \sin T A}{\cos \frac{o a 1}{2}},[o a 1=\min (o a, 180-o a)] \tag{8}
\end{gather*}
$$

For the most relevant MSs used in the trawls described in section 2.1 ( $12,20,30$ and 40 mm ) and opening angles ranging from $5-90^{\circ}$ the predicted 150 values using previously obtained each species' best model were summarized in isoline graphs. The dataset resulting from the above procedure was processed using the statistical software tool $R$ (version 4.0.0; R Core Team (2020)). All plots were produced using the ggplot2 package (Wickham 2016).

Based on the fall through measurements we estimate the selection curves for different combinations of mesh sizes and opening angles (Fig. 3).

Figure 3. Prediction of selectivity curves for a 20 mm mesh size with different opening angles.

A total of 311 pearlsides and 71 glacier lanternfish were used in the fall-through experiments to obtain a fall-through dataset for each of the 54 different mesh templates. This resulted in 16,794 and 3,834 data points for pearlside and glacier lanternfish, respectively. The logit size selection (1) fitted to each of the fall-through dataset allowed obtaining I50 and SR for each mesh template which we subsequently used to establish a predictive model for size selection of pearlsides and glacier lanternfish in trawls. From the total of 256 models tested for each species, the following model yielded smallest AICc value (latter in text referred to as the best model) for both species:

$$
\begin{align*}
l 50 & =\alpha_{1} \times M S \times O A+\alpha_{2} \times M S \times O A^{2}+\alpha_{3} \times M S \times O A^{3} \\
S R & =\beta_{1} \times M S \times O A+\beta_{2} \times M S \times O A^{2} \tag{9}
\end{align*}
$$

The model coefficients obtained for each species are presented in Table 1.

Table 1. Results for fitting the best model (9) to the fall-through size selectivity data for pearlside and lanternfish. Values in brackets represent 95\% confidence intervals.

| Species | Parameter | Factor | Value | P-value |

Using the best predictive model (9), the following design guides (Figure 4A \& 4B) were created depicting the effect of mesh size and mesh opening on size selection of pearlsides and glacier lanternfish optimally oriented when encountering trawl meshes. From both figures, we can see that decrease in mesh opening angle from $90^{\circ}$ to $\sim 40^{\circ}$ has negligible effect on the L50 values for both species. Further decrease in opening angle results in lower L50 values. The increase in mesh size from 5 mm to $\sim 30 \mathrm{~mm}$ results in greater increase in 150 values, compared to the same increase in mesh size in the $\sim 30 \mathrm{~mm}$ to 60 mm range.

Fig 4: Design guides showing the effect of MS and OA on L50 values for optimally oriented pearlside (A) and glacier lanternfish (B). Considering that pearlside and glacier lanternfish grow up to 8 cm and 10 cm , respectively, more pronounced red color on the plot indicates greater catch loss of the species.

Figures 5 \& 6 illustrate how 150 values vary with the change in mesh opening angle and angle of attack for selected mesh sizes for pearlside and lanternfish, respectively. From both figures it is evident that lower mesh sizes ( 12 mm and 16 mm ) are more suitable options for catching both species.

Figure 5. Predicted 150 values for Muller's pearlside (in mm ) for different attack angles and mesh opening angles for selected mesh sizes ( $11 \mathrm{~mm}, 17 \mathrm{~mm}, 20 \mathrm{~mm}, 24 \mathrm{~mm}, 30 \mathrm{~mm}, 40$ $\mathrm{mm})$. Considering that pearlside grows up to 8 cm , more pronounced red color on the plot indicates greater catch loss of the species.

Figure 6: Predicted 150 values for glacier lanternfish (in mm ) for different attack angles and mesh opening angles for selected mesh sizes ( $11 \mathrm{~mm}, 17 \mathrm{~mm}, 20 \mathrm{~mm}, 24 \mathrm{~mm}, 30 \mathrm{~mm}, 40$ mm ). Considering that glacier lanternfish grows up to 8 cm , more pronounced red color on the plot indicates greater catch loss of the species.
